

Admission and Routing Control with Partial Information and Limited Buffers

E. ALTMAN*, R. MARQUEZ† and U. YECHIALI‡

Abstract

We study problems of admission and routing control for loss systems comprised of a controller and C down-stream servers. We focus on problems in which control actions have to be taken with either delayed or with no information on the state of the down-stream servers. We first consider a problem of routing into C servers and compare the performance of two policies: a static round-robin policy, which does not wait for the delayed information at a risk of losing customers at the busy servers, and a Wait policy, that avoids losses at the servers but risks losses at the controller buffer. We identify regions in which each of the policies performs better. We then study the problem with no information on down-stream servers and propose a timer mechanism to decide when to dispatch an arriving customer. We optimize the value of the timer's parameter. Our study is accompanied with numerical investigations.

Keywords: Admission control, Routing control, Delayed information, Loss systems.

1 Introduction

In high speed networks propagation delay of information can not be neglected with respect to transmission delays. This is in particular the case in geosatellite satellite networks in which round-trip information delays are around 250msec. In addition, large random time varying delays are often incurred due to queueing. Many network control problems (such as routing and admission control) have therefore to take into account the information delay. In such cases we have either to take decisions without waiting for the delay or evaluate the impact of having to wait for the delays on the system performance.

In this paper we focus on admission and routing problems occurring in loss systems, in which state information is either delayed or nonavailable. The common objectives in the problems that we pose is to

‡Department of Statistics and Operations Research, School of Mathematical Sciences, Tel Aviv University, Tel Aviv 69978, Israel (uriy@post.tau.ac.il)

minimize losses (or equivalently, maximize the throughput).

We first consider a problem of routing into C servers and compare the performance of two policies:

1. The static round-robin policy, which does not wait till the delayed information on service completion arrives; it dispatches each arriving customer according to the round-robin policy at the risk of loss of that customer at the server, if it has not completed its service of the previous customer there.
2. The Wait policy, which only dispatches a job to a server once it receives the information that the server has completed service. Customers that arrive when the Wait policy is used have to queue in a finite queueing facility till they are dispatched. This policy avoids losses at the servers but results in losses when a customer arrives and finds the queueing facility full.

We evaluate the performance of both policies and show that for large delays the round robin outperforms the Wait policy, and for low delays the situation is reversed. This suggests the existence of a threshold such that for delays larger than the threshold it is better to use the round robin policies, and for delays lower than the threshold it is better to use the Wait policy. Through an extensive numerical investigation, we validate the existence of such a threshold and study its properties.

We then study the problem with no information on down-stream servers and propose a timer mechanism to decide when to dispatch an arriving customer. We optimize the value of the timer's parameter. Our study is accompanied with numerical investigations.

The structure of the paper is as follows. We introduce in the next section a brief (nonexhaustive) survey of control problems in telecommunications with delayed information. We then introduce in Section 3 the general model. Then we study in Subsection 4.1 the performance of the Wait policy and in Subsection 4.2 that of the round policies. The comparison between the policies and the existence of a threshold, obtained numerically, are the subject of Section 5. Finally the timer model is presented, analyzed and optimized in Section 6.

2 Related work

We briefly review work on control problems with delayed information in telecommunications. Flow control with delayed information has been studied in [4, 5, 10] by transforming the problem into an equivalent MDP with full information. The first paper has been extended to noisy delayed information in [3]. Two types of flow control have been studied. The first type is a rate-base flow control, in which the rate of transmission of packets is directly controlled. The second type is a window-based flow control, in which the controller adjusts its window dynamically; a window stands for the number of packets that can be sent before acknowledgements to the source arrive from the destination. Work on rate-based flow control with delay

in the framework of linear quadratic control (linear dynamics and quadratic cost) has appeared in [1] and references therein. The impact of delay on window-based flow control in the framework of Jackson network is analyzed in [7]. A problem of optimal priority assignment for access to a single channel with delay has been investigated in [2]. Routing with delayed information has been investigated in [6, 9, 11].

The model in our paper is closely related to that in [11] who also compares the performance of policies that wait for information and policies that ignore the information. The framework is however of an infinite queue and the performance measure studied is expected delays. This is in contrast to our framework in which we study finite buffers and are interested in maximizing throughputs and minimizing loss probabilities.

We finally mention some works control of communication with delayed information in the case of several decentralized controllers. The reference uses a framework known as "delay sharing information", in which the state space can be decomposed to several parts, each corresponding to another controller. Now each control has an immediate information on his own part of the state space, but a delayed information on the parts corresponding to other controllers. In [13], a decentralized control in packet switched satellite communication is studied, whereas a decentralized control problem for multiaccess broadcast networks have been studied in [8]. In both examples, each controller has to decide whether to transmit or not, without knowing if packets have arrived in the current time unit to other nodes. If they did, then packets from other nodes could be scheduled for transmission at the same time and collisions could occur.

3 Model

A single controller accepts arriving messages (jobs) and dispatches them to C down-stream servers.

Assumptions:

1. Arrivals: The external arrival is Poisson (λ) with inter arrival times $IA \sim Exp(\lambda)$ having Laplace-Stieltjes Transform (LST) $E[\exp\{-s \cdot IA\}] = \widetilde{IA}(s)$.
2. The controller: The controller has a buffer of size $N_c + 1$ (where $0 \leq N_c \leq \infty$) i.e., if $N_c = 0$, then only one job can reside in the controller's buffer. If there are $N_c + 1$ jobs in the controller's buffer and arrival occurs, it is lost.
3. The servers: The buffer of each server is of size $N_s + 1$. The service time B of each individual job is distributed $Exp(\mu)$.
4. Information: Information about service completion reaches the controller only after a random delay $V \sim Exp(\gamma)$.

We assume that all inter-arrival times, service times and information delays are independent.

We propose below several policies for the controller and compare the performances, under different assumptions on the information delay.

4 Model 1

4.1 The Wait Option

We assume here that the controller waits until he receives information on service completion before dispatching a job (if available) to a server. (In such a case there could be at most one job in each server's buffer.) This leads to the following Markovian model.

Due to the delayed information on service completions, the controller does not know the real number of jobs present in the system. We shall adopt here the view that the controller *considers a job to be "in the system" until the information on the departure of that job becomes known to the controller*. Let X denote the number of jobs "in the system" and let J denote the number of actually operating (servicing) servers. To illustrate the transitions between states consider the case $N_c = 0$. Assume that there are $J = j < C$ actual operating servers and that the controller considers there to be $X = n$ jobs in the system (clearly $n \geq j$). We denote this situation as state (j, n) . When $n = C$ and a new job arrives the job is kept at the controller's buffer and the state becomes $(j, C + 1)$. At that time there are $C - j$ servers that are free, although this information is not yet available to the controller. The remaining time till the first information on a new server becoming free arrives at the controller is exponentially distributed with parameter $(C - j)\gamma$. As soon as this information becomes available, the controller immediately dispatches the job he holds in his buffer, bringing the state of the system to $(j + 1, C)$. When $n < C$ and a job arrives it is immediately dispatched to one of the $C - n$ available servers, bringing the state of the system to $(j + 1, n + 1)$. Finally, when the controller counts $n = C + 1$, any new arrival is lost.

It should be noted that according to this policy, there are no losses at the servers' side.

Let P_{jn} be the probability that there are j operating servers and total n jobs "in the system" as counted by the controller ($j \leq \min(n, C)$; $n \leq C + N_c + 1$).

The rate-of-transition diagram for $N_c = 0$ is depicted in Figure 1, where the vertical axis denotes the number of operating servers, J , and the horizontal axis depicts the total number of jobs "in the system", X .

Figure 1: Transition rate diagram for $N_c = 0$

Balance Equations, $N_c \geq 0$

When $N_c \geq 0$, the balance equations for the state probabilities P_{jn} are the following:

$$\underline{j = 0} : \tag{1}$$

$$\begin{aligned} \lambda P_{00} &= \gamma P_{01}, & n = 0 \\ (\lambda + n\gamma)P_{0n} &= (n+1)\gamma P_{0,n+1} + \mu P_{1n}, & 1 \leq n \leq C-1 \\ (\lambda + C\gamma)P_{0C} &= \mu P_{1C}, & n = C \\ (\lambda + C\gamma)P_{0,n} &= \mu P_{1,n+1} + \lambda P_{0,n-1}, & n = C+1, \dots, C+N_c \\ C\gamma P_{0,C+N_c+1} &= \mu P_{1,C+N_c+1} + \lambda P_{0,C+N_c}, & n = C+N_c+1 \end{aligned}$$

$$\underline{1 \leq j \leq C-1} : \tag{2}$$

$$\begin{aligned} (\lambda + j\mu)P_{jj} &= \gamma P_{j,j+1} + \lambda P_{j-1,j-1} & n = j \\ (\lambda + (n-j)\gamma + j\mu)P_{jn} &= (n+1-j)\gamma P_{j,n+1} + (j+1)\mu P_{j+1,n} + \lambda P_{j-1,n-1} & j+1 \leq n \leq C-1 \\ (\lambda + (C-j)\gamma + j\mu)P_{jC} &= (j+1)\mu P_{j+1,C} + \lambda P_{j-1,C-1} + (C-j+1)\gamma P_{j-1,C+1} & n = C \\ (\lambda + (C-j)\gamma + j\mu)P_{j,n} &= (j+1)\mu P_{j+1,n} + \lambda P_{j,n-1} + (C-j+1)\gamma P_{C-1,n+1} & n = C+1, \dots, C+N_c \\ ((C-j)\gamma + j\mu)P_{j,C+N_c+1} &= (j+1)\mu P_{j+1,C+N_c+1} + \lambda P_{j,C+N_c} & n = C+N_c+1 \end{aligned}$$

$$\underline{j = C} : \tag{3}$$

$$\begin{aligned} (\lambda + C\mu)P_{CC} &= \lambda P_{C-1,C-1} + \gamma P_{C-1,C+1} & n = C \\ (\lambda + C\mu)P_{Cn} &= \lambda P_{C,n-1} + \gamma P_{C-1,n+1} & n = C+1, \dots, C+N_c \\ C\mu P_{C,C+N_c+1} &= \lambda P_{C,C+N_c} & n = C+N_c+1. \end{aligned}$$

Now, for this "wait" policy of the controller, whenever there are $n = C + N_c + 1$ jobs in the system (i.e. the controller holds $N_c + 1$ jobs in his buffer) each new arrival *will be lost*. Thus, the probability of loss is given by

$$P_{loss}(wait) = \sum_{j=0}^C P_{j,C+N_c+1} =: P_{\bullet,C+N_c+1}.$$

The mean number of losses per unit time (i.e. loss rate) is

$$\lambda P_{loss}(wait) = \lambda P_{\bullet,C+N_c+1}.$$

A limiting case Suppose $1/\gamma \rightarrow 0$. That is, the server obtains information on service completions with no delay. The state space collapses to a one dimensional space (that denotes the number of jobs in the system) and the transition diagram, for $N_c > 0$, is depicted in Figure 2.

Denoting $a = \lambda/\mu$, the balance equations are:

$$P_n = \frac{1}{n!} a^n P_0, \quad n = 0, 1, 2, \dots, C \tag{4}$$

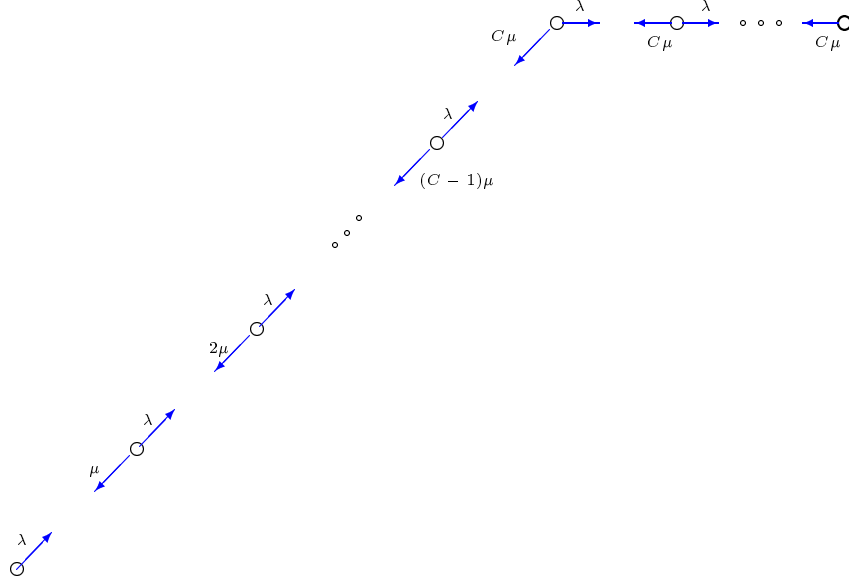

Figure 2: Transition rate diagram for $1/\gamma = 0$ and $N_c > 0$

$$P_{C+k} = \left(\frac{a}{C}\right)^k P_C, \quad k = 1, 2, \dots, N_c + 1 \quad (5)$$

As the probabilities sum to one, we get

$$P_0^{-1} = \sum_{n=0}^C \frac{a^n}{n!} + \frac{a^C}{C!} \sum_{k=1}^{N_c+1} \left(\frac{a}{C}\right)^k.$$

Thus,

$$P_{loss}(wait) = P_{C+N_c+1} = \frac{\frac{a^C}{C!} \left(\frac{a}{C}\right)^{N_c+1}}{\sum_{n=0}^C \frac{a^n}{n!} + \frac{a^C}{C!} \sum_{k=1}^{N_c+1} \left(\frac{a}{C}\right)^k}$$

The expected number of losses per unit time is $\lambda P_{loss}(wait) = \lambda P_{C+N_c+1}$.

4.2 No Wait: The Round Robin Policy

According to this policy the controller dispatches jobs following the Round Robin (RR) mechanism, that is, arrival number $kC + i$ is sent to server no. i ($k = 0, 1, 2, \dots; 1 \leq i \leq C$). Thus, the inter arrival time to each server is Erlang(C, λ) with mean C/λ . We assume that $N_s = 0$ for each server.

The probability of a loss $P_{loss}(RR)$ at a given server is the probability that the inter-arrival time is shorter than the service time B , i.e.

$$P_{loss}(RR) = P[\text{Erlang}(C, \lambda) < B] = \left(\frac{\lambda}{\lambda + \mu}\right)^C = [\tilde{\text{I}}\tilde{\text{A}}(\mu)]^C$$

Thus the expected number of losses per unit time is

$$\lambda P_{loss(RR)} = \lambda \left(\frac{\lambda}{\lambda + \mu} \right)^C.$$

5 Comparison between Wait and RR policies

5.1 The extreme cases: γ small and large

For the limiting case $1/\gamma \rightarrow 0$, i.e. when full information is available,

$$P_{loss(RR)} > P_{loss(wait)} \quad \text{iff} \quad \left(\frac{\lambda}{\lambda + \mu} \right)^C = \left(\frac{a}{a+1} \right)^C > \frac{\frac{a^C}{C!} \left(\frac{a}{C} \right)^{N_c+1}}{\sum_{n=0}^C \frac{a^n}{n!} + \frac{a^C}{C!} \sum_{k=1}^{N_c+1} \left(\frac{a}{C} \right)^k}.$$

When $N_c = 0$ this is equivalent to

$$\sum_{n=0}^C \frac{a^n}{n!} + \frac{a}{C} \cdot \frac{a^C}{C!} > \frac{a}{C \cdot C!} (a+1)^C,$$

or to,

$$\sum_{n=0}^C \frac{a^n}{n!} > \frac{a}{C \cdot C!} \left[(a+1)^C - a^C \right] \quad (6)$$

Proposition 5.1 *For the limiting case $1/\gamma \rightarrow 0$ we have: $P_{loss(RR)} > P_{loss(wait)}$ for all $C \geq 1$.*

The proof follows directly from the next two Lemmas.

Lemma 5.1 *When $N_c = 0$, $P_{loss(RR)} > P_{loss(wait)}$ for all $C \geq 1$.*

Proof. Writing $(a+1)^C = \sum_{n=0}^C \binom{C}{n} a^n$, the right hand side of (6) becomes $\frac{1}{C} \sum_{n=1}^C \frac{a^n}{(C+1-n)!(n-1)!}$. It is now easy to check that the coefficient of each power of a on the left hand side of (6) is greater than the corresponding coefficient on the right hand side. ■

Lemma 5.2 *$P_{loss(wait)}$ is monotone decreasing in N_c .*

Proof. Fix a value $N_c \geq 0$ and denote X the random variable corresponding to the number of customers in the system. Denote by X' the random variable corresponding to the number of customers in another system which differs from the original only by the fact that $N'_c = N_c + 1$. Define $Y = \max(X' - 1, 0)$ and note that Y and X have the same range of $(0, 1, 2, \dots, C + N_c + 1)$. Let

$$r_X(0) = 0, \quad r_X(n) = P(X = n - 1)/P(X = n), \quad n = 1, 2, 3, \dots, C + N_c + 1.$$

We define in the same way r_Y . Then:

$$r_X(n) = \begin{cases} n/a & n = 1, \dots, C, \\ C/a & n = C + 1, \dots, C + N_c + 1, \end{cases} \quad r_Y(n) = \begin{cases} 2(1+a)/a^2 & n = 1, \\ (n+1)/a & n = 2, \dots, C - 1, \\ C/a & n = C, \dots, C + N_c + 1. \end{cases}$$

It is easy to check that for all $n = 1, 2, \dots, N_c + C + 1$ we have

$$r_X(n) \leq r_Y(n).$$

It then follows (see e.g. [12, eq. (4)]) that $X \geq Y$ in the likelihood ratio and in the stochastic order ratio, which implies that

$$P(X = C + N_c + 1) \geq P(Y = C + N_c + 1)$$

or equivalently,

$$P(X = C + N_c + 1) \geq P(X' = C + N_c + 2).$$

This establishes the proof. ■

Remark 5.1 If $1/\gamma \rightarrow \infty$ then the controller, if waits, never dispatches jobs to the C channels and all losses are incurred by the controller, so $P_{loss}(RR) < P_{loss}(Wait)$.

5.2 A threshold policy: Numerical Results

Having seen that in the extreme cases RR is better when delays are large and Wait is better for short delays, we could expect there to be a threshold $\hat{\gamma}^*(\mu, \lambda)$ on the delay parameter such that RR is better than Wait for $\gamma < \hat{\gamma}^*(\mu, \lambda)$ and Wait is better than RR for $\gamma > \hat{\gamma}^*(\mu, \lambda)$. The existence of such a threshold will be supported by our numerical investigation. Since we can rescale time (by redefining what is a basic time unit), the threshold will be of the form:

$$\hat{\gamma}^*(\mu, \lambda) = \lambda \gamma^*(\mu/\lambda).$$

Without loss of generality we can thus choose $\lambda = 1$ and check the dependence of γ^* on μ .

The next figures analyze the case of $N_c = 0$ and $\lambda = 1$. Using Matlab, we did an exhaustive numerical study of the performance of both RR and Wait policies as a function of the parameters by solving eq. (1)-(3). We consider the case of two, three and four servers (Fig. 3,4,5 respectively).

We let γ (horizontal axis) vary from 0.01 to 10. We take six values of μ : 0.1000, 0.3162, 1.0000, 3.1623, 10.0000 and 31.6228. The vertical axis in the figures corresponds to the loss probability, and the horizontal axis to the value of the parameter γ . For each fixed μ there is one pointed horizontal line that gives the loss probability under the RR policy, and there is also a curve of the loss probability as a function of γ under the Wait policy. We see that for each value of μ , the curve describing the Wait policy intersects once the horizontal line describing the RR policy. This shows that there is indeed a threshold $\gamma^*(\mu)$ which is obtained as the intersection point.

Figure 3: Numerical analysis of loss probabilities as a function of γ and μ for both RR and Wait policies, $c = 2$ servers, $N_c = 0$ and $\lambda = 1$. The dotted horizontal lines correspond to loss probabilities under the RR policies with $P_{loss}(RR) = (\lambda/(\lambda + \mu))^c = (1/(1 + \mu))^2$. The curved lines correspond to the Wait policies.

We further see from the Figures that the threshold is *increasing* in μ . The threshold is almost linear on the log-log scale of the figure. For example, for $C = 3$ it is approximated by the empirical relation:

$$\log(P_{loss}(RR)) = -3.8253 \times \log(\gamma) - 0.9972.$$

If we did not take a log-log scale we would see clearly that the threshold as a function of μ is almost constant for μ in the range of 0.2-4 and its value is close to one.

Figure 4: Numerical analysis of loss probabilities as a function of γ and μ for both RR and Wait policies, $c = 3$ servers, $N_c = 0$ and $\lambda = 1$.

6 Model 2: A Timer

We introduce the following Timer policy:

As soon as the controller dispatches a job to a server, he activates a Timer, having a random duration T .

We consider the case where the controller obtains no information on service completions. The first arrival during T (if occurs) is held in the controller's buffer and released for service at time T . Subsequent jobs within T (if any) are lost. If the first arrival after a dispatching occurs beyond T , it is sent immediately to one of the servers and a new Timer is activated. Moreover, if a job is dispatched to a server and the latter is busy, the job is lost.

The problem is to find the value (or the distribution) of T so as to minimize the total rate of losses, both at the controller's and the servers' side.

$C = 1$ servers

We consider first the case $C = 1$ and assume that the down-stream server may hold only one job, i.e.,

Figure 5: Numerical analysis of loss probabilities as a function of γ and μ for both RR and Wait policies, $c = 4$ servers, $N_c = 0$ and $\lambda = 1$

$N_s = 0$. We further assume that the controller can hold only one job: $N_c = 0$.

Let τ be the time between two consecutive dispatches of jobs to the server. Let R be the time interval from the moment of dispatching till the first arrival thereafter occurs. R is either the full inter-arrival time (if the moment of dispatching occurs immediately upon arrival), or it is the residual Inter-Arrival time (if the moment of dispatching occurs when the timer had expired previously and there was a job in the controller's buffer). In both cases, due to the Poisson arrival, R has an exponential distribution with parameter λ . Thus, $\tau = \max(R, T)$.

The probability of loss at the server is given by

$$P_{loss}(server) = P(\tau < B) = \tilde{\tau}(\mu)$$

where $\tilde{\tau}$ is the Laplace-Stieltjes transform of τ . Since the rate of arrival to the server is $1/E[\tau]$, the rate of losses at the server's barrier is $\tilde{\tau}(\mu)/E[\tau]$. On the other hand, the rate of losses at the controller's entrance is $\lambda - 1/E[\tau]$. The total rate of losses is thus

$$\frac{\tilde{\tau}(\mu)}{E[\tau]} + \lambda - \frac{1}{E[\tau]}.$$

The throughput is then

$$\text{THP} = \lambda - \{\text{total rate of losses}\} = \frac{1 - \tilde{\tau}(\mu)}{E[\tau]}.$$

We now wish to find T that maximizes THP.

A Deterministic Timer, $C = 1$.

When T is a fixed constant $T = T_0$, then

$$P(\tau \leq t) = \begin{cases} 0 & \text{for } t < T_0, \\ 1 - \exp(-\lambda t) & \text{for } t \geq T_0. \end{cases}$$

Hence

$$\tilde{\tau}(\mu) = \int_0^\infty e^{-\mu t} dP(\tau \leq t) = \int_{t=T_0}^\infty e^{-\mu t} \lambda e^{-\lambda t} dt = \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)T_0},$$

and

$$E[\tau] = \int_0^\infty [1 - P(\tau \leq t)] dt = T_0 + \frac{1}{\lambda} e^{-\lambda T_0}.$$

So

$$\text{THP} = \frac{1 - \tilde{\tau}(\mu)}{E[\tau]} = \frac{1 - \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)T_0}}{T_0 + \frac{1}{\lambda} e^{-\lambda T_0}} \quad (7)$$

To obtain the maximum throughput, we compute the derivative of THP at zero and obtain the condition

$$\left(\lambda T_0 + \frac{\lambda}{\lambda + \mu} \right) e^{-(\lambda + \mu)T_0} + \frac{\mu}{\lambda + \mu} e^{-(2\lambda + \mu)T_0} = 1 - e^{-\lambda T_0}.$$

One can easily see that this equation has a unique finite solution $T_0 > 0$.

An Exponential Timer, $C = 1$.

In case T is exponentially distributed with parameter ξ . We have

$$P(\tau \leq t) = P(\max(T, \text{IA}) \leq t) = P(T \leq t)P(\text{IA} \leq t) = 1 - e^{-\lambda t} - e^{-\xi t} + e^{-(\lambda + \xi)t}.$$

Thus

$$\tilde{\tau}(\mu) = \int_0^\infty e^{-\mu t} dP(\tau \leq t) = \frac{\lambda}{\lambda + \mu} + \frac{\xi}{\xi + \mu} - \frac{\lambda + \xi}{\lambda + \xi + \mu},$$

and

$$E[\tau] = \frac{1}{\lambda} + \frac{1}{\xi} - \frac{1}{\lambda + \xi} = \frac{1}{\lambda} + \frac{\lambda}{\xi(\lambda + \xi)}.$$

Hence the throughput is given by

$$\text{THP} = \frac{1 - \tilde{\tau}(\mu)}{E[\tau]} = \frac{\frac{\mu}{\lambda + \mu} - \frac{\xi}{\xi + \mu} + \frac{\lambda + \xi}{\lambda + \xi + \mu}}{\frac{1}{\lambda} + \frac{\lambda}{\xi(\lambda + \xi)}}. \quad (8)$$

Note that when there is no timer ($\xi \rightarrow \infty$) then

$$\lim_{\xi \rightarrow \infty} \text{THP}(\xi) = \frac{1}{\frac{1}{\lambda} + \frac{1}{\mu}}.$$

Indeed, the expected interval between two successive job-departures equals $\frac{1}{\lambda} + \frac{1}{\mu}$ since any job sent to the server during service is lost, so that after a service completion (having mean $1/\mu$) it takes, on average, $1/\lambda$ units of time for the next arrival.

On the other hand, if $\xi \rightarrow 0$ then $E[\tau]$ tends to infinity and, obviously, the throughput tends to zero.

Numerical results In Figure 6 we plot the optimal value of the timer T_0 and of the exponentially average timer value $T_0 = \xi^{-1}$ as a function of μ . We see that it decreases in μ , and becomes almost constant for $\mu \geq \lambda/10$. We also depict the throughputs obtained under the optimal timer. We clearly see that the deterministic timer always outperforms the exponential one.

Figure 6: Optimal threshold value and throughput of the deterministic and exponential timers as a function of μ

$C > 1$ servers

When $C > 1$, the controller dispatches arriving jobs to the various servers in a cyclic (i.e. Round Robin) fashion. After each dispatch he activates a Timer T . If an arrival occurs before T , the controller keeps it in its buffer. All subsequent arrivals within T are lost. If there is a job in the controller's buffer at time T , it

is dispatched according to the RR policy. If not, the first arrival thereafter is immediately dispatched and the controller activates a new Timer.

Let τ be the time between two consecutive dispatches. As before, $\tau = \max(R, T)$ where R is the time interval from a moment of dispatching until first arrival there-after. Recall that R is exponentially distributed with parameter λ .

The rate of loss at the controller's entrance is, as before, $\lambda - 1/E[\tau]$.

The rate of loss at the servers is calculated as follows. Since service times B are Exponential (μ),

$$P_{loss}(\text{any single server}) = P\left(\sum_{j=1}^C \tau_j < B\right) = [\tilde{\tau}(\mu)]^C.$$

As the rate of arrival to any single sever is $\frac{1}{CE[\tau]}$, the total rate of loss for all C servers and the controller is

$$\frac{C[\tilde{\tau}(\mu)]^C}{CE[\tau]} + \left(\lambda - \frac{1}{E[\tau]}\right).$$

The throughput is the external arrival rate, λ , minus the total loss rate:

$$\text{THP} = \frac{1}{E[\tau]} - \frac{[\tilde{\tau}(\mu)]^C}{E[\tau]} = \frac{1 - [\tilde{\tau}(\mu)]^C}{E[\tau]}.$$

As examples, for T exponential with parameter ξ we obtain

$$[\tilde{\tau}(\mu)]^C = \left[\frac{\lambda}{\lambda + \mu} + \frac{\xi}{\xi + \mu} - \frac{\lambda + \xi}{\lambda + \xi + \mu} \right]^C$$

and as before,

$$E[\tau] = \frac{1}{\lambda} + \frac{\lambda}{\xi(\lambda + \xi)}$$

so that

$$\text{THP}(exp) = \frac{1 - \left[\frac{\lambda}{\lambda + \mu} + \frac{\xi}{\xi + \mu} - \frac{\lambda + \xi}{\lambda + \xi + \mu} \right]^C}{\frac{1}{\lambda} + \frac{\lambda}{\xi(\lambda + \xi)}}. \quad (9)$$

When $C = 1$, equation (9) reduces to (8).

For $T = T_0$ deterministic, we have

$$[\tilde{\tau}(\mu)]^C = \left(\frac{\lambda}{\lambda + \mu} \right)^C e^{-C(\lambda + \mu)T_0},$$

and

$$E[\tau] = T_0 + \frac{1}{\lambda} e^{-\lambda T_0},$$

so

$$\text{THP}(deterministic) = \frac{1 - \left(\frac{\lambda}{\lambda + \mu} \right)^C e^{-C(\lambda + \mu)T_0}}{T_0 + \frac{1}{\lambda} e^{-\lambda T_0}}. \quad (10)$$

Again, when $C = 1$ equation (10) reduces to (7). Also, as for the case $C = 1$, the optimal value T_0 can be calculated by differentiation.

Numerical results In Figures 7-9 we plot the optimal value of the timer T_0 and of the exponentially average timer value $T_0 = \xi^{-1}$ as a function of μ , for the cases of $C = 2$ to $C = 4$ respectively. We see that it decreases in μ , and becomes almost constant for $\mu \geq \lambda/10$. We also depict the throughputs obtained under the optimal timer. We see again that the deterministic timer always outperforms the exponential one. Without loss of generality, we have considered only the case of $\lambda = 1$.

Figure 7: Optimal threshold value and throughput of the deterministic and exponential timers as a function of μ , $C = 2$

For $C = 3$ and $C = 4$ it is better not to use a timer in the case of exponentially distributed time: the value of $T_0 = 1/\xi$ is 0 for all tested values of μ !

7 Conclusion

We have studied in this paper two main aspects of delay that appear in admission and routing control. The first type is that of the information available to the controller. To study the relevance of the information after a delay, we have studied the performance of the admission policy that wait till the information becomes available in order to take an action (Wait policy) and compared it to the one that does not wait to get that information (RR policy). We obtained a clear threshold on the expected delay above which the RR policy

Figure 8: Optimal threshold value and throughput of the deterministic and exponential timers as a function of μ , $C = 3$

has better performance (lower loss probability) and below which the Wait policy is superior.

We then studied another role of delay, when the delay is itself a control action. In absence of any information on the system state, we showed that delaying packets at the input buffer before routing them to the network results in better performance of the system (lower losses). We computed the optimal deterministic and exponentially distributed delays which minimize the loss rate and maximize the system's throughput.
