Edge-Forming Methods for Color Image Zooming
Youngjoon Cha and Seongjai Kim

Abstract—This paper introduces edge-forming schemes for image zooming of color images by general magnification factors. In order to remove/reduce artifacts arising in interpolation, such as image blur and the checkerboard effect, an edge-forming method is suggested to be applied as a postprocess of standard interpolation methods. The method is based on nonconvex nonlinear partial differential equations. The equations are carefully discretized, incorporating numerical schemes of anisotropic diffusion, to be able to form reliable edges satisfactorily. The alternating direction implicit (ADI) method is employed for an efficient simulation of the model. It has been numerically verified that the resulting algorithm can form clear edges in 2 to 3 ADI iterations. Various results are given to show the effectiveness and reliability of the algorithm.

Index Terms—Anisotropic diffusion, checkerboard effect, edge forming, image zooming, interpolation.

I. INTRODUCTION

IMAGE interpolation is the first of two basic resampling steps and turns a discrete image into a continuous function, which is necessary for various geometric transform of discrete images. There are two kinds of interpolation methods: linear and nonlinear ones. For linear methods, diverse interpolation kernels of finite size have been introduced, in the literature, as approximations of the ideal interpolation kernel (the sinc function) which is spatially unlimited; see [11], [17], and [28]. Two of the simplest approximations are related to the nearest-neighbor interpolation and the bilinear interpolation. Higher order interpolation methods involving larger number of pixel values have shown superior properties for some classes of images. However, most of the linear interpolation methods have been introduced without considering specific (local) information of edges. Thus, they bring up the smoothing effect in resulting images. Furthermore, when the image is zoomed by a large factor, the zoomed image looks blocky; such a phenomenon is called the checkerboard effect. Recently, some nonlinear interpolation methods have been suggested to reduce the artifacts of linear methods [3], [13], [18]. The major step in the nonlinear methods is to either fit the edges with some templates or predict edge information for the high resolution image from the low resolution one.

A color image is usually represented as a three-dimensional vector such that each component represents intensity of RGB (red, green, and blue) three colors. For color image denoising, we first observe the work of Sapiro and Ringach [24] and Blomgren and Chan [1], [2]. Recently, the variational method has been generalized to nonflat features [5], [6], [16], [22], [25], [26], [27].

In this paper, we are interested in the development of edge-forming methods to be applied as a postprocess of standard image zooming methods for color images, with the hope of removing the checkerboard effect. As the model, we consider a system of nonlinear partial differential equations (PDEs) in the angle domain, which can be viewed as a variant of the model in Vese and Osher [29]. Then, separable anisotropic numerical schemes are incorporated for the model to form reliable edges. The alternating direction implicit (ADI) method is adopted to compute the resulting algebraic system efficiently.

For a closely related method, see a total variation (TV)-based interpolation method suggested by Guichard and Malgouyres [12]. See also [19], where some linear and nonlinear interpolation methods are analyzed mathematically and experimentally, including the TV-based interpolation.

An outline of the paper is as follows. In the next section, we briefly review an effective edge-forming model for grayscale images, which has been suggested by the authors [4]. Section III contains an extension of the edge-forming method for color images. For a choice of edge-forming model, we have modified the model of Vese and Osher [29], which was first introduced for $p$-harmonic flows and its application to denoising. The ADI method is employed, as an iterative procedure for the integration in the direction of artificial time. In Section IV, a new constraint parameter is considered in order for the new algorithm to be able to form edges for image zooming by general (noninteger) magnification factors. Section V shows numerical experiments; our new algorithm turns out to be able to form clear edges for various color images, satisfactorily in 2 to 3 ADI iterations. The last section concludes our development and experiments.

II. PRELIMINARIES

In this section, we briefly review an effective edge-forming technique, suggested by the authors [4], as a postprocess of standard interpolation methods for grayscale images.

A. Nonlinear Semi-Discrete Model

Let $I^0$ be a given image which is zoomed by one of linear interpolation methods. Then, we can write

$$u^0 = u + r$$

where $u$ is the desired image (hopefully, having sharp and reliable edges) and $r$ denotes the noise involved during the in-
terpolation and resampling. Consider the following nonlinear semi-discrete model of the form
\[
\frac{\partial u}{\partial t} + A u = \beta (u^0 - u)
\]  
(1)

where \( \beta \) denotes a constraint parameter and \( A = A(u) \) is a diffusion matrix, i.e., for \( A = (a_{rs}) \)
\[
a_{rs} \leq 0, \quad r \neq s, \quad a_{rr} = \sum_{s \neq r} |a_{rs}| > 0, \quad \forall r.
\]

The diffusion must be anisotropic and carefully designed in order to preserve and construct reliable edges.

Note that the recovered image \( u \) becomes closer to \( u^0 \) as \( \beta \) grows. When images are to be magnified by an integer factor \( k_1 \times k_2 \), one can manage the interpolation algorithm such that the values at each \( (k_1 \times k_2) \)th pixel can be assigned directly from the original image without approximation. It is then desirable that we try not to alter those original values during the postprocessing of edge forming. Thus, we may set \( \beta \) in (1) large at the pixels of original values and let \( \beta = 0 \) elsewhere. In this paper, such \( \beta \) is said to be \textit{two-valued}.

For an efficient simulation of (1), we will select \( A \) separable, i.e., \( A = A_1 + A_2 \)

where \( A_1 \) and \( A_2 \) are submatrices that represent connections of pixel values in the horizontal and vertical directions, respectively. In Section II-B, we will show an explicit construction of the diffusion matrix that shows an ability to form edges. We first consider an efficient (linearized) time-stepping procedure for (1).

Denote the timestep size by \( \Delta t \). Set \( \theta = n \Delta t \) and \( \theta^n = u(\cdot, \theta^n) \) for \( n \geq 0 \). Then, the problem can be linearized by evaluating the matrix \( A(u) \) from the previous time level. Consider the linearized \( \theta \) method for (1) of the form
\[
\frac{u^n - u_\theta^{n-1}}{\Delta t} + (A^{n-1} + \beta I)[\theta u^n + (1 - \theta)u_\theta^{n-1}] = \beta u^0, \quad 0 \leq \theta \leq 1
\]  
(2)

where \( A^{n-1} = A(u_\theta^{n-1}) \). Note that the \( \theta \) method turns out to be the explicit, the implicit, and the Crank–Nicolson methods, respectively, for \( \theta = 0, \theta = 1, \) and \( \theta = 1/2 \). Let
\[
B^{n-1}_\ell = A^{n-1}_\ell + \frac{1}{2} \beta I, \quad \ell = 1, 2.
\]

Then, the ADI method [7]–[10], [21] is a perturbation of (2), with a splitting error of \( O(\Delta t^2) \)
\[
[1 + \theta \Delta t B^{n-1}_1] u^n = [1 - (1 - \theta) \Delta t B^{n-1}_1 - \Delta t B^{n-1}_2] u_\theta^{n-1} + \Delta t \beta u^n
\]
\[
[1 + \theta \Delta t B^{n-1}_2] u^n = u^n + \theta \Delta t B^{n-1}_2 u_\theta^{n-1}
\]  
(3)

where \( u^n \) is an intermediate solution. Note that when the matrices \( A^{n-1}_k \) are composed with a three-point stencil, each sweep in (3) can be carried out by inverting a series of tri-diagonal matrices.

B. Anisotropic Edge-Forming Schemes

We will consider an effective edge-forming scheme for \( A_1 \) for anisotropic diffusion (AD); it is straightforward to apply the same scheme for \( A_2 \).

Let \( x_{ij} \) be the \( ij \)th pixel in the image and \( u_{ij} = u(x_{ij}) \). We construct the row of \( A^{n-1}_1 \) corresponding to the pixel \( x_{ij} \), \( [A^{n-1}_1]_{ij} \), which consists of three consecutive nonzero elements which represent the connection of \( u_{ij} \) to \( u_{i-1,j} \) and \( u_{i+1,j} \)
\[
[A^{n-1}_1]_{ij} = \begin{pmatrix} -a_{ij}W^{n-1}_1 & a_{ij}E^{n-1}_1 & 0.5 \end{pmatrix}
\]  
(4)

where
\[
a_{ij}W^{n-1}_1 = \frac{2d_{ij,E_1}^{n-1}}{d_{ij,E_1}^{n-1} + d_{ij,E_1}^{n-1}}, \quad a_{ij}E^{n-1}_1 = \frac{2d_{ij,E_1}^{n-1}}{d_{ij,E_1}^{n-1} + d_{ij,E_1}^{n-1}}.
\]  
(5)

We wish to determine \( d_{ij,E_1}^{n-1} \) and \( d_{ij,E_1}^{n-1} \) in such a way that the algorithm (2) can form edges. Let
\[
d_{ij,W_1}^{n-1} = \left[ \left( D u^{n-1}_{i-1/2,j} \right)^2 + \varepsilon \right]^{q/2}, \quad q \geq 0
\]
\[
d_{ij,E_1}^{n-1} = d_{i+1,j}W^{n-1}_1
\]  
(6)

where the regularization parameter \( \varepsilon > 0 \) has been introduced to prevent the denominator in (4) from approaching zero and \( D u^{n-1}_{i-1/2,j} \) is to be defined as finite difference approximations of \( \nabla u^{n-1} \) evaluated at \( x_{i-1/2,j} \) the midpoint of \( x_{i-1,j} \) and \( x_{i,j} \)
\[
D u^{n-1}_{i-1/2,j} = \left( u^{n-1}_{i,j} - u^{n-1}_{i-1,j} \right)^2 + \left( u^{n-1}_{i,j} + u^{n-1}_{i+1,j} \right)^2 - \left( u^{n-1}_{i-1,j} + u^{n-1}_{i,j} \right)^2 \right]^{1/2}
\]  
(7)

The numerical realization of the model (1), the \( \theta \) method (2) incorporating the schemes (4)–(7), has shown an excellent per-
formance for edge forming for two-dimensional images when 
$q \in [1,3,1.8]$ (a heuristic finding). It has been also observed
from various numerical experiments that the resulting algorithm
does not exhibit apparent differences depending on angles of
image features ("rotational invariance"), although the diffusion
matrix $A$ is separable. The authors [4] analyzed stability for the
$\theta$ method, as in the following two theorems.

**Theorem 2.1:** [4]: Suppose that the image is to be magnified
by a factor of $k_1 \times k_2$, where $k_1$ and $k_2$ are positive integers.
Let the $\theta$ method (2), $0 \leq \theta \leq 1$, incorporate the edge-forming
schemes (4)–(7) and satisfy the following condition:

$$4(1 - \theta) \Delta t \leq 1. \quad (8)$$

Suppose the solution of (2), $u^n$, have a local maximum or
minimum at a point $\bar{x}_{ij}$ where $\beta = 0$. Then, it is constant, for
all $q \geq 0$, on the block of $(k_1 \times k_2)$ pixels that contains the
point $\bar{x}_{ij}$.

**Theorem 2.2:** [4]: Let the $\theta$ method (2), $0 \leq \theta \leq 1$, incorporate
the edge-forming schemes (4)–(7) and satisfy

$$\theta \geq \frac{1}{2}, \quad (4 + \beta)(1 - \theta) \Delta t \leq 1. \quad (9)$$

Then

$$\max_{\beta \geq 0} \| u^n_{ij} - u^0_{ij} \|_\infty \leq \frac{4}{4 + \beta} \| u^0 \|_\infty, \quad n \geq 1. \quad (10)$$

For instance, if it is desired for $|u^n_{ij} - u^0_{ij}|$ to be not larger
than 1% the given image $u^0$ at the pixels where $\beta > 0$, one
should choose $\beta \geq 306$ (for the numerical results in Section V,
we set $\beta = 1000$ for the two-valued $\beta$).

III. EDGE-FORMING METHODS FOR COLOR IMAGES

A. Interpretation for the Semi-Discrete Model

We begin with a numerical interpretation for the semi-discrete
model (1) and the edge-forming schemes (4)–(7), from which
we will try to obtain motivation for an effective model for color
image zooming. The schemes can be obtained from a numerical
approximation of a diffusion operator of the term

$$-\left( \frac{u^n}{\sqrt{|u^n - 1|}} \right)_x^q, \quad q \geq 0$$

where $\sqrt{|u^n|} = \sqrt{u^n_x^2 + u^n_y^2 + \epsilon^2}$. Indeed, the scheme can be obtained with the following differences:

$$\left( \frac{u^n_{ij}}{\sqrt{|u^n - 1|}} \right)_x^q \approx \frac{1}{d_{ij,W}} u_{ij}^{n-1} - u_{ij}^{n} + \frac{1}{d_{ij,E}} u_{ij}^{n+1} - u_{ij}^{n}$$

$$\left( \frac{u^n_{ij}}{\sqrt{|u^n - 1|}} \right)_y^q \approx \frac{1}{d_{ij,W}} u_{ij}^{n-1} - u_{ij}^{n} + \frac{1}{d_{ij,E}} u_{ij}^{n+1} - u_{ij}^{n}$$

Thus, the discrete model (1) incorporating the anisotropic edge-
forming schemes (4)–(7) can be viewed as a linearized spatial
discretization of the following nonlinear PDE

$$\frac{\partial u}{\partial t} - \nabla u \cdot q \nabla \left( \frac{\nabla u}{\sqrt{|\nabla u|}} \right) = \beta(u^0 - u), \quad q \geq 0 \quad (12)$$

which is a variant of the denoising PDE model suggested by
either Rudin et al. [23] (the TV model) or Marquina and Osher [20].

B. Edge-Forming Model for Color Images

For edge-forming schemes for color images, we have been
motivated from the observation in Section III-A. In this section,
we will first consider a denoising model for color images and
then it will be modified and approximated to be able to form
edges.

In the RGB representation, a color image is a mapping

$$I: \Omega \rightarrow \mathbb{R}^3 = \{(r,g,b): r,g,b \geq 0\}$$

which can be decomposed into brightness and chromaticity

$$\eta(x) = \| I(x) \|, \quad (\text{brightness})$$

$$\varphi(x) = \frac{I(x)}{\| I(x) \|} = \frac{I(x)}{\eta(x)}, \quad (\text{chromaticity}) \quad (13)$$

where $\| \cdot \|$ is the least-squares ($L^2$) norm. Thus, the brightness
$\eta$ represents the length of the RGB color vector, and the
chromaticity $\varphi$ denotes the normalized color component, which lies
on the unit sphere $S^2$. In [5] and [6], it has been verified that in
denoising, the use of the chromaticity-brightness (CB) decom-
position results in better restored images than conventional
approaches such as the channel-by-channel model and the HSV
system.

The brightness can be treated as the same way as for grayscale
ingages, applying the edge-forming model (1). On the other
hand, we need to develop an appropriate mathematical model
to handle the chromaticity effectively in the angle domain.

Based on the elegant mathematical work by Vese and Osher
[29], Kim [15] has experimented an angle domain algorithm to
denoise color images efficiently and reliably. Let $v = \eta u = (u,v,w)$ and

$$\varphi = \tan^{-1} \left( \frac{w}{\sqrt{u^2 + v^2}} \right), \quad \xi = \tan^{-1} \left( \frac{v}{u} \right)$$

(it should be noted that $u,v,w \geq 0$ and, therefore, $0 \leq \varphi, \xi \leq \pi/2$; there is no difficulty for the issue of “2\pi-modulo”). Associated
with the minimization problem

$$\min_v \int_\Omega \left| \nabla \left( \frac{v}{|v|} \right) \right|^p \, dx \quad (14)$$
the Euler–Lagrange equations in the angle domain read [15], [29]

\[ -\nabla \cdot \left( \frac{\nabla \varphi}{R(\varphi, \xi)^{2-p}} \right) = \frac{\sin \varphi \cos \xi}{R(\varphi, \xi)^{2-p}} |\nabla \xi|^2 \\
-\nabla \cdot \left( \frac{\cos^2 \varphi \nabla \xi}{R(\varphi, \xi)^{2-p}} \right) = 0 \]  

(15)

where

\[ R(\varphi, \xi) = \sqrt{\nabla \varphi^2 + \cos^2 \varphi |\nabla \xi|^2 + \varepsilon^2}, \quad \varepsilon > 0. \]

Here, we have introduced the regularization term \( \varepsilon > 0 \) to prevent the denominators in (15) from approaching zero.

To get an edge-forming model for the chromaticity components, we 1) multiply both sides of the equations in (15) by \( R(\varphi, \xi)^{2-p} \), 2) introduce an artificial time \( t \) for the parameterization of the energy descent direction, and 3) impose a constraint term. It should be noted [20] that the scaling will not make the stationary solution of the resulting model differ from that of (15) by a significant amount.

Then, the complete set of edge-forming model, including the equation for the brightness, can be formulated as follows: Find \((\eta, \varphi, \xi)\) by solving

\[ \frac{\partial \eta}{\partial t} - |\nabla \eta|^q \nabla \cdot \left( \frac{\nabla \eta}{|\nabla \eta|^p} \right) = \beta(\eta^0 - \eta) \]

\[ \frac{\partial \varphi}{\partial t} - R(\varphi, \xi)^{q} \nabla \cdot \left( \frac{\nabla \varphi}{R(\varphi, \xi)^{p}} \right) = \sin \varphi \cos \xi |\nabla \xi|^2 \\
+ \beta(\varphi^0 - \varphi) \]

\[ \frac{\partial \xi}{\partial t} - R(\varphi, \xi)^{q} \nabla \cdot \left( \frac{\cos^2 \varphi \nabla \xi}{R(\varphi, \xi)^{p}} \right) = \beta(\xi^0 - \xi) \]  

(16)

where \( q = 2 - p \), \( \beta \geq 0 \), and \((\eta^0, \varphi^0, \xi^0)\) denotes an initialization of \((\eta, \varphi, \xi)\).

C. Anisotropic Edge-Forming Schemes for Color Images

For the discretization of the diffusion terms in the chromaticity equations in (16), we adopt the idea of the edge-forming schemes for grayscale images presented in Sections II-B and III-A. We first define \( d_{ij,W}(c)^{n-1} \) and \( d_{ij,E}(c)^{n-1} \), as the counterparts of \( d_{ij,W}^{n-1} \) and \( d_{ij,E}^{n-1} \) in (6)

\[ d_{ij,W}(c)^{n-1} = \left[ D_{ij,W}^{n-1} + C_{ij,W}^{n-1} \left( D_{ij,W}^{n-1} \right)^2 + \varepsilon^2 \right]^{q/2} \]

\[ d_{ij,E}(c)^{n-1} = d_{i+1,j,W}(c)^{n-1} \]  

(17)

where \( D \) is defined as in (7) and

\[ C_{ij,W}^{n-1} = \cos^2 \varphi_{i-1/2,j}^{n-1} \quad C_{ij,E}^{n-1} = C_{i+1,j,W}^{n-1}. \]

Then, for the chromaticity components, the counterparts of \( a_{ij,W}^{n-1} \) and \( a_{ij,E}^{n-1} \) in (5) can be defined as

\[ a_{ij,W}(c)^{n-1} = \frac{2 d_{ij,W}(c)^{n-1}}{d_{ij,W}(c)^{n-1} + d_{ij,E}(c)^{n-1}} \]  

(φ)

\[ a_{ij,E}(c)^{n-1} = \frac{2 d_{ij,E}(c)^{n-1}}{d_{ij,W}(c)^{n-1} + d_{ij,E}(c)^{n-1}} \]  

(ξ).  

(18)

Equation (18), as well as (5), complete the construction of \( A_{ij}^{(c),n-1} \) as in (4), where \( \phi \) denotes \( \eta, \varphi \), or \( \xi \). One can construct \( A_{ij}^{(c),n-1} \) similarly.

Thus, for each component, one can compute the solution in the new level \( \phi^n \) by employing the ADI (3) as follows:

\[ \left[ 1 + \theta \Delta t B^{\phi,n-1}_2 \right] \phi^n = \left[ 1 - (1 - \theta) \Delta t B^{\phi,n-1}_2 - \Delta t B^{\xi,n-1}_2 \right] \phi^{n-1} + \Delta t (Q^{\phi,n-1} + \beta \phi^0) \]

\[ + \left[ 1 + \theta \Delta t B^{\xi,n-1}_2 \right] \phi^n = \phi^0 + \theta \Delta t B^{\phi,n-1}_2 \phi^{n-1} \]  

(19)

where \( B^{\phi,n-1}_2 = A^{\phi,n-1}_\ell + \beta/2, \ell = 1,2 \), and

\[ Q^{\phi,n-1} = Q^{\xi,n-1} = 0 \]

\[ Q^{\phi,n-1} = \sin \varphi^{n-1} \cos \xi^{n-1} |\nabla_h \xi^{n-1}|^2. \]

Here, \( \nabla_h \) denotes a finite difference approximation of \( \nabla \) (in this paper, we adopt the second-order central scheme for it). We will call (19) the \( \theta \)-ADI.

A) Remark: When the image is magnified by a large factor, e.g., 8 × 8, one may try to enlarge the image by three recursive applications of 2 × 2 magnification and edge-forming rather than once 8 × 8 magnification followed by edge forming. For the interpolation alone, a recursive application introduces no observable improvement/difference from the image of one-time application, for most cases. On the other hand, the edge-forming algorithm turns out to be able to develop reliable edges in 2 to 3 \( \theta \)-ADI iterations for image zooming by magnification factors of 2 to 3, while it requires a relatively larger number of iterations for image zooming by factors \( \geq 4 \). Thus, one can speed up the simulation by a recursive application of smaller factors, because the earlier recursions are applied to smaller images and, therefore, much more efficient in computation. It also has been verified for recursive applications of edge forming to improve the quality of resulting images (see [4]).

IV. NEW CHOICE OF \( \beta \)

When the image is magnified by a factor of \( k_1 \times k_2 \), where \( k_1 \) and \( k_2 \) are positive integers, one can manage the interpolation algorithm such that the values at each \((k_1 \times k_2)\)th pixel can
be assigned directly from the original image without approximation. Then, we must set $\beta$ in (1) large at the pixels of original values not to alter them (see Theorem 2.2). At other pixels, one may set $\beta$ small or simply zero, which allows the values alter easily. However, such a strategy might not be applicable for image zooming by general (noninteger) factors, because it is rare for the values in the original image to be directly assigned to the zoomed image without approximation. In this section, we will introduce an effective strategy to overcome the difficulty.

We begin with an observation on the checkerboard effect. For simplicity, consider a grayscale image which is magnified by the bilinear interpolation by an integer factor, as in Fig. 1. The checkerboard effect appeared in the interpolated image [Fig. 1(b)] is originated from the image blocks on each of which the image is bilinear. Consider the quantity $[\Delta \phi]$, where $\Delta$ denotes the Laplacian and $\phi^0$ is the interpolated image. Then, it is not difficult to verify that for each image blocks, the quantity must be zero at interior pixels and its local maximum appears at one of the four corner points. The more dramatic changes the image has, the larger the Laplacian is at the corners (and the sides) of the image blocks.

The above observation has motivated an effective strategy for the choice of $\beta$, given as follows:

$$\beta = \alpha |\Delta \phi|^\delta$$

(20)

where $\alpha$ and $\delta$ are positive parameters to be determined and $\phi$ is $\eta$, $\varphi$, or $\xi$. The parameter $\alpha$ is introduced for a global scaling of $\beta$, while $\delta$ must put an emphasis of $\beta$ on the corner pixels when $\delta > 1$. Unfortunately, we do not know of any rigorous analysis for the choice of $\alpha$ and $\delta$. Here is a guideline for their choices from various numerical experiments: Set $\delta = 3 \sim 5$ and choose $\alpha$ such that the maximum of $\beta$ is about 1000 (for the numerical results presented in Section V, we set $\delta = 4$ and select the scaling factor $\alpha$ such that $\max_{i,j} \beta_{ij} = 1000$ for each of the three color components).

Note that the strategy in (20) does not require information on the pixels whether the image values are original or not; it works along with information integrated from the image Laplacian only. With the strategy, every bilinear image block is a candidate for modification to form reliable edges, based on the minimization principle in (14). Thus, there is no guarantee to set $\beta$ sufficiently large to tightly keep the original image values during the edge forming. However, since $\beta$ is relatively large at pixels where the image content varies rapidly, and since the edge-forming schemes in Section III-C can form reliable edges fast, the strategy is applicable for various situations, in particular, for image zooming by general (noninteger) magnification factors. In this paper, we call the parameter $\beta$ in (20) the image-Laplacian constraint (ILC) parameter.

When the image is magnified by a bicubic interpolation, the Laplacian now may not be zero at the interior pixels of image blocks. Thus, one may consider the quantity $[\Delta \phi^0]$, which guarantees $\beta$ to become zero at the interior pixels of image blocks. However, the Laplacian is still a favorable choice for $\beta$; it has been experimentally verified that the ILC parameter is better than the one from the fourth-order differential operator for most real images we have tested.

V. NUMERICAL EXPERIMENTS

This section presents numerical experiments carried out with the $\theta$-ADI (19), the edge-forming schemes discussed in Section III-C, and the parameter choice in Section IV. We select $q = 1.7$ in (17) and $\delta = 1$ and $\theta = 0.5$ for the $\theta$-ADI. The choice of $q$ is heuristic: it turns out to be insensitive enough for a predetermined value to be utilized for various images. It has been analyzed that the quantity $\Delta \phi^0$ is not only a step to but also a parameter for the algorithm to be able to reduce more effectively a certain range of frequency components in the image (see [14] for details).

In Fig. 2, we test performances of the new edge-forming algorithm performing for a synthetic color image. Fig. 2(a) is the original image containing $60 \times 60$ pixels and it is magnified by a bicubic interpolation as in Fig. 2(b). Fig. 2(c) and (d) depict enlarged images obtained by three recursive applications of the $2 \times 2$ bicubic interpolation and edge forming with the two-valued $\beta$ and the ILC parameter in (20), respectively. For each recursion, three $\theta$-ADI iterations are applied. As one can see from the figure, the cubic interpolation has revealed a severe checkerboard effect and the edge-forming algorithm can form reliable edges in just three $\theta$-ADI iterations, with the ILC parameter performing better than the two-valued $\beta$.

Fig. 3 presents an example which shows how the edge-forming algorithm affects other features, i.e., features that are not edges. The smooth image incorporates three features: a sphere (yellow), a swollen-up square (purple), and a magnitude-change with a gradually increasing curvature from top right to bottom left (in grayscale). As one can see from Fig. 3(d), the change made by the edge-forming algorithm is negligible, except for the region of large curvatures (the bottom left of the magnitude-change). There, the algorithm has tried to form an edge, which one can also see from a comparison between Fig. 3(b) and (c). It has been observed from this example and others that the edge-forming algorithm forms edges in the regions where the curvature is large, while it may alter smooth regions by a negligible amount.
Fig. 2. Synthetic color disk: (a) the original image in 60 × 60 pixels, (b) a bicubicly interpolated image by a factor of 8 × 8, (c) the edge-formed image with the two-valued $\beta$, and (d) the edge-formed image with the ILC parameter. (Color version available online at http://ieeexplore.ieee.org.)

Fig. 3. Synthetic color image: (a) the original image in 80 × 80 pixels, (b) a bicubicly interpolated image by a factor of 5 × 5, (c) the edge-formed image with the ILC parameter, and (d) an amplified difference between images in (b) and (c): $3 \cdot \left[ \frac{1}{5} (b) - (c) \right] + 128$. (Color version available online at http://ieeexplore.ieee.org.)

In Fig. 4, we continue investigating the performance of the edge-forming algorithm for a real image, Cherry, in 85 × 85 pixels. We have carried out the same experiment as in Fig. 2, except setting the magnification factor 4 × 4. Consequently, two recursive applications of 2 × 2 magnification are applied for image zooming and edge forming. For real images, we have reached the same conclusion for the performance of the edge-forming algorithm, as in Fig. 2. It is efficient and its results are reliable; the ILC parameter in (20) performs satisfactorily and better than the two-valued parameter.

For numerical results in the remainder of the section, we utilize the ILC (20) for the constraint parameter.

In Fig. 5, we present an example for the performance of the anisotropic edge-forming algorithm for general magnification factors. The original Lena Face is in 100 × 100 pixels and it is magnified by the bicubic interpolation as depicted in Fig. 5(b) (the enlarged image is in 374 × 374 pixels). The interpolated image is utilized to get an edge-formed image [Fig. 5(c)]. As one can see from the figure, the edge-forming algorithm has eliminated the checkerboard effect in the interpolated image and formed reliable edges. For this example, each of pixel values in Fig. 5(b) and (c) is approximated; none of them are directly assigned from the original image.

Fig. 6 contains images of Cat Face. The original image is in 60 × 65 pixels and it is magnified by 2π × 2π, by the bicubic interpolation [Fig. 6(b)] and by two recursive applications (π × π followed by 2 × 2) of zooming and edge forming [Fig. 6(c)]. As expected, the edge-formed image shows clear and reliable edges, although some texture information for hair has been missed during the anisotropic diffusion of edge forming.

For the above example, one may apply the recursive application in the opposite order: magnification by a factor of 2 × 2
followed by $\pi \times \pi$. The resulting images show no significant differences.

For a more systematic analysis for the edge-forming algorithm, we shrink a selected set of images (see Fig. 7) by $2 \times 2$ or $4 \times 4$, magnify by the same factors, and then measure the peak signal-to-noise ratio (PSNR) defined as

$$\text{PSNR} \equiv 10\log_{10} \left( \frac{\sum_{i,j} (I^0_{ij} - I_{ij})^2}{\sum_{i,j} (I^0_{ij})^2} \right) \text{ dB}$$

where $I^0$ is the original image and $I$ denotes the recovered image. As shown in Table I, the edge-forming algorithm improves the PSNR for all cases. The improvement is greatest for the grayscale synthetic image in Fig. 7(a), while the improvement for the real image in Fig. 7(c) is negligible. We believe that it is due to a denoising feature of the algorithm. The image is denoised during the edge-forming operations. However, the edge-formed images have shown clear edges as in previous examples; the anisotropic edge-forming algorithm improves the image quality significantly, in practice.

Finally, we compare the angle domain model (16) with the classical channel-by-channel model where each of three channels is treated as a grayscale image. In Fig. 8, we present the result of zooming (by a factor of $\sqrt{14} \times \sqrt{14}$) and edge forming, for Lena in Fig. 5(a), carried out with the channel-by-channel model. As one can see from Fig. 8 and from Fig. 5(b) and (c),
the channel-by-channel model introduces altered colors into the resulting image. This example is consistent with the claim in [5] and [6]: The use of the chromaticity-brightness decomposition results in better restored images than the channel-by-channel model.

VI. CONCLUSION

In image zooming, the image is first interpolated and then resampled for higher resolution images. This paper has introduced
a new edge-forming algorithm to remove/reduce artifacts (such as image blur and the checkerboard effect) arising in image interpolation for color images. The method is based on nonlinear PDEs which result from the minimization of a nonconvex functional of the image gradient. Anisotropic diffusion has been incorporated through the numerical discretization of the model. For an efficient simulation of the model, we have employed the alternating direction implicit (ADI) method which is known to be very efficient in solving diffusion equations defined on rectangular domains. A new choice has been considered for the constraint parameter to be able to form edges for image zooming by general (possibly, noninteger) magnification factors. The resulting algorithm has been tested for various synthetic and real images; it can form reliable edges satisfactorily in 2 to 3 ADI iterations for image zooming by integer and noninteger factors, for both grayscale and color images.

ACKNOWLEDGMENT

The authors would like to thank the anonymous referees for their constructive and helpful suggestions.
